Abstract- **This paper presents our development of a synthetic traffic model for Microsoft Xbox System Link traffic. The goal is a traffic model that can be used by researchers and Internet Service Provider engineers to estimate the potential future impact of Xbox traffic over IP networks. We developed our ns2 simulation model for System Link traffic by running live network experiments and characterising the observed packet length, packet inter-arrival times, and data rates (in packets- and bits- per second). Our observations are documented in this paper, and we expect our traffic model will assist network planners who wish to better support real-time game traffic.**

I. INTRODUCTION

In recent years interactive network games have become more popular with Internet users and constitute an increasingly important component of the traffic seen on the Internet. Interactive game traffic has different characteristics to the WWW and e-mail traffic prevailing on the Internet today and therefore imposes different requirements on the underlying network.

Providing premium service to the increasing on-line gaming community could be a promising source of revenue for ISPs. To provide this service an ISP must have knowledge of the traffic load offered by game traffic to provision their networks accordingly. Some researchers have already looked at the traffic characteristics of different popular on-line games to provide a suitable traffic model to test existing or planed network for their capability to support game traffic [1] - [3].

We chose to investigate Halo, a very popular Xbox System Link game. Even though the System Link feature has been designed to work only over LANs, several tunneling solutions are available to connect Xboxes over the Internet [4]-[6]. In addition, the newly released Xbox Live allows Xboxes to be directly connected to the Internet without the use of tunneling [7]. This variety of different solutions and the reported success of Xbox Live [8], give an indication that ISPs might observe a substantial amount of Xbox traffic over their networks.

This paper presents the main traffic characteristics of Halo and a ns2 [9] traffic model for Xbox server and client based on these observed traffic patterns.

II. TRAFFIC CHARACTERISTICS OF HALO

A. *Experiments and set-up*

Several experiments were carried out to obtain a valid range of data points for the traffic pattern analyses. The System Link feature allows up to 4 Xboxes to be linked together via a hub over a LAN, with 1 to 4 players attached to each Xbox. Xbox System Link uses standard UDP/IP/Ethernet packets to transmit its data over the LAN. However, the IP address and UDP port of every Xbox is fixed to 0.0.0.1 and 3074 (making the packets un-routable over the Internet) and each Xbox uses MAC addresses to differentiate between the clients and server Xboxes.

We performed experiments with 2, 3 and 4 Xboxes with various combinations of players connected to each Xbox. The maximum number of players participating in an experiment was 14.

In addition to the Xboxes, a packet sniffer machine was attached to the hub to monitor the traffic generated on the LAN. An example experiment setup is shown in Figure 1

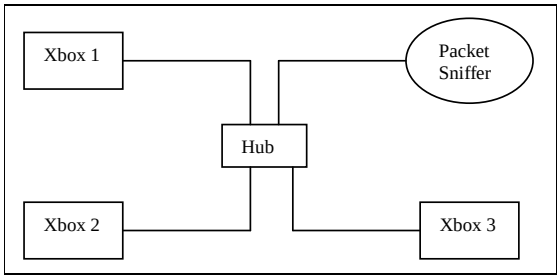

Figure 1: experimental set-up

The packet sniffer machine was a 600 MHz Celeron with 128 MB of RAM and was running the FreeBSD 4.6 operating system. The network card used was Intel Pro 10/100B/100+ Ethernet and was accessed through the 'fpx0' interface. The hub used was a 10Mbit/sec CentreCOM AT-MR820TR hub; therefore the LAN bandwidth was limited to 10 Mbps for all experiments. Tcpdump [10] was run on the packet sniffer machine to obtain a raw packet trace of the entire LAN traffic during each experiment.

To test the packet capturing and time stamping capabilities of the sniffer machine, NetCom Systems SmartBits 2000 with a SX-7410B line card was used. The SmartBits 2000 was configured to send long (500 and 1000 packet) bursts of back-to-back packets to the sniffer computer, with intervals ranging from 12.5 usec to 50 msec. We found that the computer was easily capable of time stamping within ten microseconds accuracy, even when subjected to bursts of 1000 packets spaced tens of microseconds apart. This was considered sufficient accuracy for our Xbox analysis, since we are discussing intervals to the nearest millisecond.

Pkthisto [11] was used to analyse these raw packet traces. Pkthisto creates packet length and packet inter-arrival time histograms for each flow observed in the tcpdump file. Source and destination IP addresses and

port numbers specify a flow. Because the IP addresses in System Link Ethernet frames are meaningless, pkthisto uses 4 bytes of the MAC address to derive a artificial source and destination 'IP addresses' when isolating client to server and server to client flows. Pkthisto also records data rates in packets per second (PPS) and in Kbits per second (Kbps) for each flow. We configured pkthisto to use 2000 consecutive packets for each histogram and pps/rate estimate. By default a flow is considered active if more than 200 packets are seen in less than 800 ms. In addition to per flow statistics, pkthisto can also create aggregate histograms based on all traffic to or from a specific node on the LAN.

B. *Packet lengths*

The packet lengths discussed in this section are the lengths of the IP datagrams. The UDP payload is 28 bytes shorter and the Ethernet frame 14 bytes longer than the IP datagram length.

Server to Client

The packets sent from the server Xbox to all the client Xboxes are of constant length. The only parameter governing the packet length is the total number of players in the game (N). The packet length (in bytes) is related to the number of players by the following equation:

$$Pk\_length = 30*N + 100$$

Client to Server

Two types of packets are transmitted form each client Xbox to the server. Approximately 16 % of the client to server packets have a fixed length of 72 bytes. These packets have been observed in all experiments and are independent of how many Xboxes or players participated in the games.

The length of the remaining 84% of the client to server packets is dependent on the number of players connected to a particular client Xbox (C). The packet length can be approximated by:

$$Pk\_length = 30*C + 80$$

A comparison between the measured packet lengths and the lengths obtained by the equations for server to client and client to server packets is shown in Figure 2.

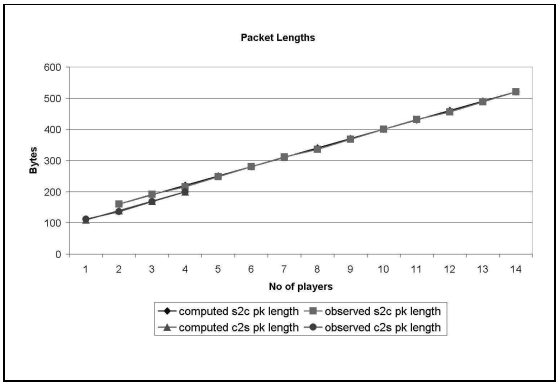

Figure 2 comparison of analytical and measured packet lengths

C. *Packet inter-arrival times*

Server to Client

The server Xbox sends update packets to each of the clients every 40 ms. The packets to all client Xboxes are transmitted back-to-back. If L clients are connected to the server during a particular game, the server sends a burst of L data packets every 40 ms. The inter-arrival histograms therefore display a value of (100*(L-1)/L)% close to 0 ms and the rest of the inter-arrival times will be concentrated around 40 ms. Figure 3 presents packet inter-arrival times for a 3 Xbox game (2 clients, 1 server) where 50 % of the packet inter-arrivals are close to 0 ms and the other 50% close to 40 ms, while Figure 4 shows the inter-arrival times for a 4 Xbox game in which 66.6% of the packets are sent out back-to-back. The symbols 'IH nn' labeling one axes in each inter-arrival time plot signify the histogram number assigned to this particular histogram by pkthisto. Each histogram consists of 2000 observed packets.

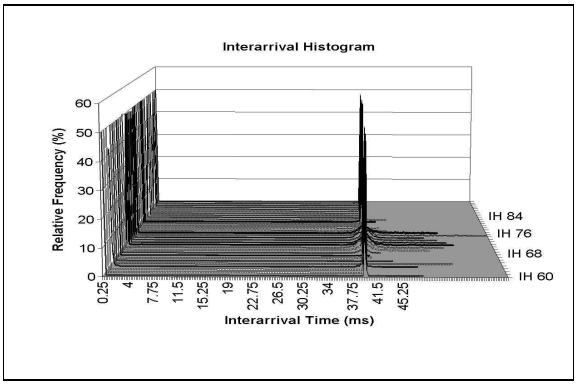

Figure 3: aggregate server to clients packet inter-arrival times (3 Xbox game)

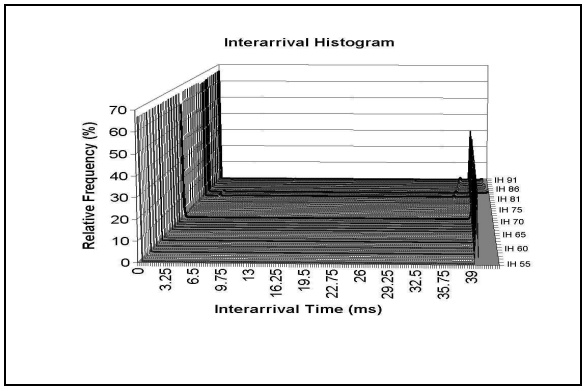

Figure 4: aggregate server to clients packet inter-arrival times (4 Xbox game)

Client to Server

The packet inter-arrival of an individual client to server data flow is independent of the number of players on the console and also independent of the number of other clients in the game. Therefore the individual client to server inter-arrival time histograms look the same for all the experiments performed and an example is shown in Figure 5.

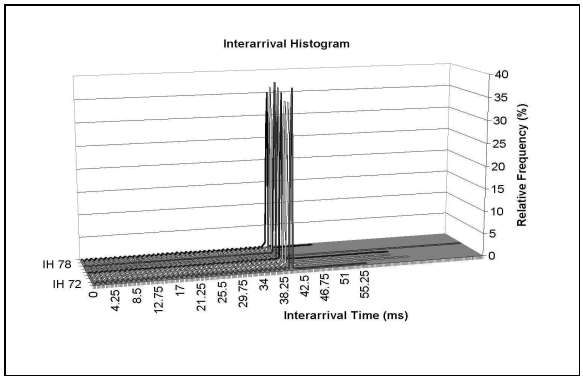

Figure 5: individual client to server packet inter-arrival time

Figure 6 presents the cumulative inter-arrival times for the same data flow (CIH nn signifies the n^{th} cumulative inter-arrival histogram created by pkthisto). In this figure it can be seen that about 33% of the packets are sent closer spaced than 40 ms. The inter-arrival time distribution for these packets is uniformly random for inter-arrival times between 0 and 40 ms (Figure 5). The remaining 67% of data packets are sent at 40 ms intervals. This uniform distribution between 0 and 40 ms is caused by the concurrent transmission of 72 byte packets every 201 ms and the packets dependent on the number of client players every 40 ms. The inter-arrival times between these 2 kinds of packets can be anywhere between 0 and 40 ms.

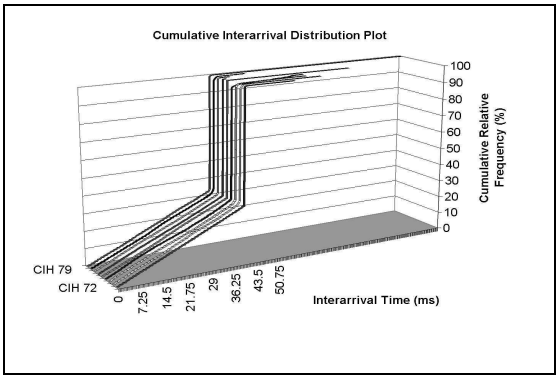

Figure 6: individual client to server cummulative packet inter-arrival times

The aggregate inter-arrival time pattern is dependent on the client Xbox hardware. Some Xboxes transmit packets at exactly 40 ms intervals, while the transmission time of other Xboxes are shifted a small random amount to the left or right. We present the graphs for the experiments with 3 Xboxes, because of their better readability. The aggregate inter-arrival times for 4 Xbox games follow the same pattern.

Figure 7 presents a game in which 2 Xboxes (X1 and X2) that transmit packets at exactly 40 ms intervals were used as clients. X1 starts transmitting 10 ms into the game, its next packet is transmitted at 50ms, and the next at 90ms. X2 starts at 40ms with packets following at 80ms, 120ms. Since X1 and X2 both transmit packets every 40 ms, the gaps in the inter-arrival times remain the same from start to finish, resulting in the two lines at approximately 10 ms and 30 ms presented in the plot.

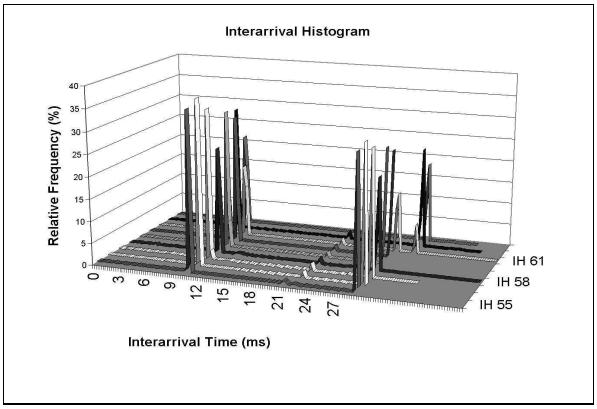

Figure 7: aggregate packet inter-arrival times fror clients x1 and x2

Figure 8 shows a packet inter-arrival time plot for a game where the transmission times for the 2 client Xboxes (X2 and X3) are slightly shifted. Because of this shift the gaps in the inter-arrival times shift during the game causing the diamond shaped pattern.

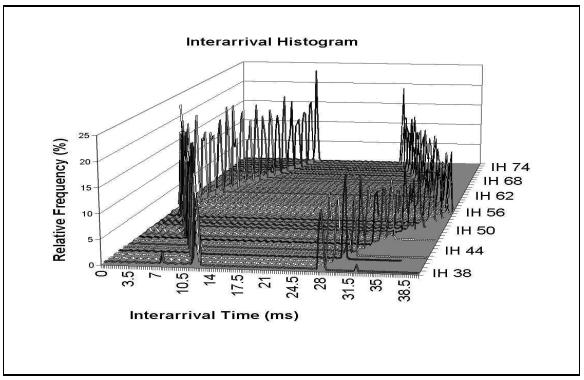

Figure 8: aggregate client to server packet inter-arrival times for clients x2 and x3

D. Data rates (in PPS and kbps)

The number of packets sent per second remaind constant throughout all experiments conducted. PPS form the server to individual clients was 25 and aggregate server to client PPS was L*25 where L is the number of clients in the game. Individual client to server PPS was 30 and the aggregate client to server PPS was always equal to L*30.

Data rates in Kbits per second are of course equal to PPS * pk-length and are therefore dependent on the number of total players for server to client flows and dependent on the number of players connected to the client Xbox for client to server flows. When discussing the packet lengths , we stated that pkhisto measures the length of the IP datagrams. The data rates presented here are therefore the rates of the IP traffic not the Ethernet traffic. A 14 byte header needs to be added to obtain the Ethernet packet lengths and the corresponding data rates.

Figure 9 shows the data rate estimated by pkthisto

for the aggregate server to clients flow, the aggregate client to server flow and one individual client to server flow for a 4 Xbox game with 4 players.

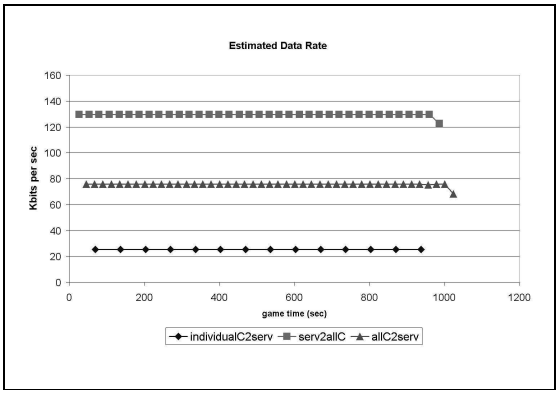

Figure 9: data rates in Kbits per sec (estimated by pkthisto)

The estimated data rate for the aggregate server to all client flow is mostly equal to 129 kbps. For a 4 player game the server sends 216 byte packets and since 3 client Xboxes are present the PPS is 75, which results in a data rate of 129.6 kbps

For the aggregate client to server flow and the individual client to server flow the same connection between packet sizes and PPS values is true as for the server to client flows. The individual client to server data rate is 25 kbps most of the time. The client to server PPS is 30; 25 packets per second are 112 bytes long (since one player is connected to the client) and 5 packets are the 72 byte long packets that are present in every game. These packet lengths and packet per second rates give 25.28 kbps. The aggregate client to server data rate is around 75 kbps, which is the sum of the individual client to server flows.

The knowledge of the packet per second rate and the packet length of the UDP payload, which is 28 bytes less than the IP datagram size, can be used to compute the expected data rate of Xbox traffic over any kind of underlying network. This is especially useful for users wanting to use an IP tunnel from their home to participate in a network game. IP tunneling enables System Link games via the Internet by transparently transmitting the Xbox traffic between the source and destination LAN.

III. SIMULATION MODEL BASED ON THE TRAFFIC CHARACTERISTICS

The goal of our study was to developed traffic models that accurately describe System Link games. These models can be used to estimate the expected performance of an Xbox game over the Internet and to help ISPs when provisioning their network services. To achieve this, the traffic generated by the simulation model should be almost indistinguishable form traffic genarated by a real Xbox. We needed to process ns2 packet traces with pkthisto to be able to make this comparison. This was achieved by implementing a small program converting ns2 trace files into tcpdumps. The resulting dumps were fed into pkthisto to create the graphs in Figure 10 to Figure 12.

A copy of the ns2 Xbox client and server models as well as the program to convert ns2 packet traces into tcpdumps can be obtained from the GENIUS web-site [12]

Packet lengths are modeled according to the formulae presented section II.B. The accuracy of these formulae compared to the actual data is already discussed in these sections.

The server model transmits a burst of 'number of clients' packets every 40 ms. The aggregate server to client inter-arrival times created by the server model in an 3 Xbox game (2 clients) are shown in Figure 10, which corresponds well to the observed traffic pattern in Figure 3.

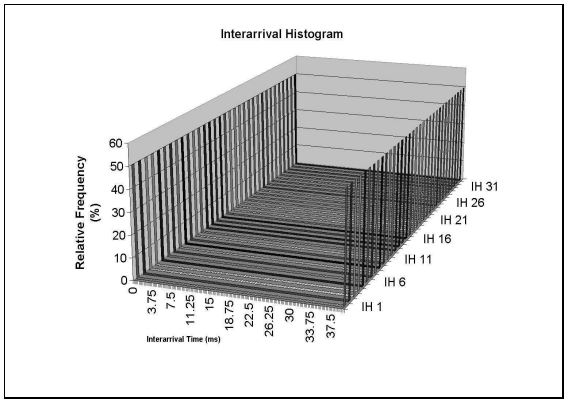

Figure 10: aggregate server to client packet inter-arrival times (ns2 mdoel)

A parameterized Xbox client model was created, which enables the user to specify a small shift in the transmission time. If the shift is specified as zero packets are transmitted at exactly 40 ms intervals. The following pseudo code represents the main Xbox client functionality. As described in section II.B, the client transmits two independent packet streams. The packet sizes of the first stream are dependent on the number of players connected to the client and packets are transmitted every 40 ms plus the specified shift. The second stream transmits 72 B long packets every 201 ms. Whenever one of the two timer expires a corresponding packet is transmitted and the timer is rescheduled.

```
sizePl = 30*nrOfPlayers + 80;.
SizeFix = 72;
intervalPl = 0.04 + shift;
intervalFix = 0.201;
timerPl.resched(intervalPl)
timerFix.resched(intervalFix)
```

Figure 11 and Figure 12 show the aggregate client to server packet inter-arrival times for two different 3 Xbox games. For the game in Figure 11 the two clients transmit the data packet at a slightly different rate, resulting in the diamond shaped inter-arrival time pattern also observed in Figure 8. Figure 12 on the other had shows the inter-arrival time pattern of a game where both clients transmit their data packets at exactly the same rate, equivalent to the game presented in

Figure 8.

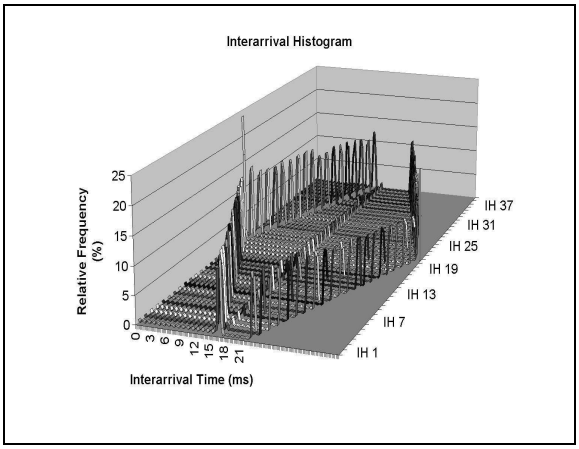

Figure 11: aggregate client to server packet inter-arrival times, 2 different transmission rates (ns2 mdoel)

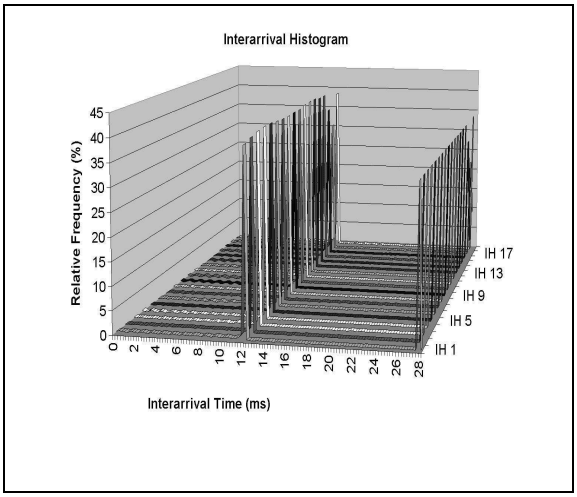

Figure 12: aggregate client to server packet inter-arrival times, same transmission rate (ns2 mdoel)

IV. CONCLUSION

Inter-active network games are very popular and can be a promising source of revenues for ISPs. To be able to offer premium service to the customers, it is important to understand the traffic characteristics of games to provision the network accordingly.

In the study presented in this paper we investigated the Xbox System Link game Halo. We found System Link traffic to be very periodic and were able to develop a simulation model that accurately reproduces the main characteristics of a System Link game. This simulation model can be used in the design of new QoS networks especially tailored to support real-time applications.

Although Xbox System Link currently only supports inter-connection via LANs, programs such as XBConnect allow System Link games to be bridged over the Internet. The newly released Xbox Live will support Xbox connections over the Internet without the use of tunneling.
